Writing X86 Code Directly

Assembly Directives

Begin with a dot and indicate structural information useful to the assembler, linker, or debugger.

- indicates label *main* is a global symbol that can be accessed by other code modules.

```
.globl main
```

- store instructions following directive in the text segment of memory

```
.text
```

- store declared data following directive in the data segment of memory

```
.data
```

- allocate space for an 8 byte value and initialize to 0

```
i: .quad 0
```

- allocate space and initialize to specified null-terminated string

```
str: .string "Enter a value"
```

Lab Assignment

simple.c: (C code)

```
#include <stdio.h>
```

```
long total = 0;
```

I

```
int sum(int x,int y) {
```

```
    int t = x + y;  
    total +=t;  
    return t;
```

```
}
```

```
int main() {
```

```
    int x = 2;  
    int y = 3;  
    printf("Sum =  
%d\n",sum(x,y));  
    printf("Total =  
%d\n",total);  
    return 0;
```

```
}
```

simple.s: (X86 code)

```
.data //use the data segment of memory
```

```
.globl total //total is a global variable
```

```
total: .quad 0 //8 bytes with initial value 0
```

```
fstr1: .string "Sum = %d\n"
```

```
fstr2: .string "Total = %d\n"
```

```
.text
```

```
.globl main
```

```
sum:
```

```
    lea (%rsi,%rdi,1),%eax  
    add %eax,total  
    ret
```

```
main:
```

```
    mov $0x3,%esi  
    mov $0x2,%edi  
    call sum
```

```
    mov %eax,%esi  
    mov $fstr1,%edi  
    mov $0x0,%eax  
    call printf
```

```
    mov $total,%esi  
    mov $fstr2,%edi  
    mov $0x0,%eax  
    call printf
```

```
    mov $0x0,%eax  
    ret
```

```
#include <stdio.h>
int z;

int square(int n) {
    return n*n;
}

int main() {
    int x = square(3);

    int y = square(4);
    z = x + y;

    printf("Calculation produces %d\n",z);
    return 0;
}
```

```
.data
    .globl z
z:   .long 0
fstr: .string "Calculation produces %d\n"

.text
    .globl main

square: mov %edi,%eax
        imul %edi,%eax
        ret

main:  push %rbx
        mov $3,%edi
        call square
        mov %eax,%ebx
        mov $4,%edi
        call square
        lea (%ebx,%eax,1),%esi
        mov %esi,z
        mov $fstr,%edi
        mov $0,%eax
        call printf
        mov $0,%eax
        pop %rbx
        ret
```

One-dimensional arrays

Different languages use different implementations at the machine level to represent data structures.

In Java, arrays are actually implemented as arrays of addresses (pointers) to the elements, which are stored elsewhere in memory (not necessarily in contiguous locations).

In C, the elements of the array are stored in a contiguous block, starting at the base address of the array.

In the C model,

```
address of element in array = base address + element size * index
```

If the size of the element is limited to 1, 2, or 4 bytes, what is another more efficient way to accomplish the multiplication?

In C, to define some arrays of 8 elements of different sizes:

```
quad qelements[] = {0xF, 0xE, 0xD, 0xC};  
int elements[] = {0x1, 0x3, 0x5, 0x7, 0x9, 0x11, 0x13, 0x15};  
short welements[] = {0x23, 0x25, 0x27, 0x29, 0x31, 0x33, 0x35, 0x37}  
byte belements[] = {0x20, 0x30, 0x40, 0x50, 0x60, 0x70, 0x80, 0x90}
```

The equivalent in X86 is:

```
.data  
qelements: .quad 0xF,0xE,0XD,0XC  
elements: .long 0x1, 0x3, 0x5, 0x7, 0x9, 0x11,0x13,0x15  
welements: .word 0x23,0x25,0x27,0x29,0x31,0x33,0x35,0x37  
belements: .byte 0x20,0x30,0x40,0x50,0x60,0x70,0x80,0x90
```

The contents of memory starting at *qelements* displayed using *gdb* would look something like this:

```
0x0049700 <qelements>: 0x00000000 0x0000000F 0x00000000 0x0000000E  
0x8049714 <qelements+16>: 0x00000000 0x0000000D 0x00000000 0x0000000C  
0x0049724 <elements >: 0x00000001 0x00000003 0x00000005 0x00000007  
0x0049734 <qelements+16>: 0x00000009 0x00000011 0x00000013 0x00000015  
0x0049744 <welements >: 0x00250023 0x00290027 0x00330031 0x00370035  
0x 049754 <belements >: 0x50403020 0x90807060
```

Two-dimensional arrays

In C, when nested array of arrays are used, each row is stored contiguously in memory (*row-major* format), and the address of an element can be calculated by the following formula (size of row is the number of columns in a row):

```
address of element[row][col] =  
    base address of array +  
    (row * size of row * size of element) +  
    (col * size of element)
```

-or-

```
base address of array +  
(row*size of row + col)*size of element
```

In C, to define a 4x4 array of integers:

```
int twodarr[4][4] = {{0x1, 0x2, 0x3, 0x4},  
                     {0x4, 0x6, 0x7, 0x8},  
                     {0x9, 0x10, 0x11, 0x12},  
                     {0x13, 0x14, 0x15, 0x16}};
```

The equivalent in X86 is:

```
.data  
twodarr: .long 0x1, 0x2, 0x3, 0x4  
.long 0x5, 0x6, 0x7, 0x8  
.long 0x9, 0x10, 0x11, 0x12  
.long 0x13, 0x14, 0x15, 0x16
```

Either would be displayed using *gdb* as:

```
0x80497a0 <twodarr>: 0x00000001 0x00000002 0x00000003 0x00000004  
0x80497b0 <twodarr+16>: 0x00000005 0x00000006 0x00000007 0x00000008  
0x80497c0 <twodarr+32>: 0x00000009 0x00000010 0x00000011 0x00000012  
0x80497d0 <twodarr+48>: 0x00000013 0x00000014 0x00000015 0x00000016
```
